We discuss both theoretically and experimentally elementary two-photon polarization entanglement localization after break of entanglement caused by linear coupling of environmental photon with one of the system photons. The localization of entanglement is based on simple polarization measurement of the surrounding photon after the coupling. We demonstrate that non-zero entanglement can be localized back irrespectively to the distinguishability of coupled photons. Further, it can be increased by local single-copy polarization filters up to an amount violating Bell inequalities. The present technique allows to restore entanglement in that cases, when the entanglement distillation does not produce any entanglement out of the coupling.

I. INTRODUCTION

Quantum entanglement, the fundamental resource in quantum information science, is extremely sensitive to coupling to surrounding systems. By this coupling the entanglement is reduced or even completely vanishes. In the case of partial entanglement reduction, quantum purification and distillation protocols can be adopted [1, 2, 3, 4, 5]. In quantum distillation protocols, entanglement can be increased without any operation on the surrounding systems. Using a collective procedure, the distillation probabilistically transforms many copies of less entangled states to a single more entangled state, using a collective procedure just at the output of the coupling [6]. Fundamentally, the distillation requires at least a bit of residual entanglement passing through the coupling.

When the coupling with the environment completely destroys the entanglement, both purification and distillation protocols can not be exploited. Hence another branch of methods like unlocking of hidden entanglement [7] or entanglement localization [8, 9, 10, 11, 12] must be used. In reference [7] there has been estimated that in order to unlock the hidden entanglement from a separable mixed state of two subsystems an additional bit or bits of classical information is needed to determine which entangled state is actually present in the mixture. However no strategy was presented in order to extract this information from the system of interest or the environment. Latter, to retrieve the entanglement, the localization protocols [8, 9, 10, 11, 12] have been introduced working on the principle of getting some nonzero amount of bipartite entanglement from some multipartite entanglement. That means performing some kind of operation on the multipartite system (or on its part) may induce bipartite entanglement between subsystems of interest.

We can say that the entanglement breaks because it is so inconveniently redistributed among system of inter-

est and environment that it is transformed into generally complex multipartite entanglement. Entanglement can be localized back for the further application just by performing suitable measurement on the surrounding system and the proper feed-forward quantum correction. The measurement and feed-forward operation substitute, at least partially, a full inversion of the coupling which requires to keep very precise interference with the surrounding systems. For many-particle systems, the maximal value of the localizable entanglement depends on the coupling and also on initial states of surrounding systems.

To understand the mechanism of the entanglement localization, we simplify the complex many particle coupling process to a set of sequential couplings with a single particle representing an elementary surrounding system E [13]: see FIG. 1. Then, our focus is just on the three-qubit entanglement produced by this elementary coupling of one qubit from maximally entangled state of two qubits A and B to a third surrounding qubit E . Before the coupling to the qubit B , we have typically no control on the quantum state of qubit E , hence considered to be unknown. Further, the qubit E is typically not interfering or weakly interfering with the qubit B . Recently Sciarrino et al. [14] reported the entanglement localization after the coupling to an incoherent noisy system.

In this paper, we report the study in depth of the key role of two-photon *interference* in the process of entanglement localization presented in our previous paper [14]. In particular we focus on the theory of the localization protocol, both considering a distinguishable and an indistinguishable photon coupling with the environment. The experimental implementation of such processes will be presented as well, with large attention to the experimental setup. In order to carry out our analysis on the dynamic of the localization protocol, we have considered a simple process for the interaction between the signal photon and the surrounding one. To be specific, we assume a polarization insensitive linear coupling between

FIG. 1: (Color online) **a)** Schematic representation of the localization protocol. **b)** Detailed representation of the three steps of the localization procedure.

distinguishable or partially distinguishable surrounding unpolarized single photon E and single photon B from the photon pair A, B maximally entangled in the polarization degree of freedom. After this coupling, the state of two entangled photons A, B turns to be a mixture of the two-photon maximally entangled state and the separable two unpolarized photons. For some value of the coupling, this state gets separable and the entanglement is completely redirected to the surrounding system. We theoretically prove that for any linear coupling, it is always possible to localize a non-zero entanglement back to the photon pair A, B just by a polarization sensitive detection of the photon E . Interestingly, this qualitative result can be obtained irrespectively to the level of distinguishability and noise in the surrounding photon E . We discuss the impact of distinguishability in the entanglement localization more in details and give physical explanation of the differences between the localization for distinguishable or partial distinguishable photon E . The performance of this localization can be further enhanced using a simple single-copy distillation method [15, 16, 17, 18, 19, 20, 21, 22, 23, 24], up to a state violating Bell inequalities [25, 26], independently on the noise and distinguishability of the photon E .

The paper is organized as follows. In Sec. II we discuss theory of the polarization entanglement localization, for a comparison, first for the coupling of fully indistinguishable photons (Sec. II.A) and then for realistic linear cou-

pling of partially distinguishable photons (Sec. II.B). In Sec. III, the experimental results are discussed in details. The Sec. III.A describes the experimental setup and the state preparation. The Sec. III.B contains the experimental result about the localization for the coupling of fully distinguishable photons, the Sec. III.C presents the results of localization for the coupling of indistinguishable photon whereas the Sec. III.D reports on results of localization for the coupling of partially indistinguishable photons. The summary is done in the Conclusion. In the Appendix A, a modification of the entanglement localization for the polarizing linear coupling is described.

II. THEORY

Let us assume that we generate a maximally entangled polarization state $|\Psi_{-}\rangle_{AB} = (|HV\rangle - |VH\rangle)/\sqrt{2}$ of two photons A and B . The form of the maximally entangled state is not relevant, as the same results can be obtained for any maximally entangled state. The first photon is kept by Alice and second is coupled to the surrounding photon E in an unknown state, $\rho_E = \mathbb{1}/2$ (completely unpolarized state), by a simple linear polarization insensitive coupling (a beam splitter with transmissivity T). After the coupling, three possible situations can be observed: both photons B and E go simultaneously to either mode k'_B or mode k'_E , or only a single photon is separately presented in both output modes k'_B or k'_E (see FIG. 1). We will focus only on the last case, that is a single photon output from the coupling. In this case, it is in principle not possible to distinguish whether the output photon is the one from the entangled pair (B) or the unpolarized photon E . We investigate in detail, the impact of the distinguishability of the surrounding system on the localization procedure. Note that the system E can be also produced by the entanglement source and then coupled to the entangled state through a subsequent propagation. Therefore, it is not fundamentally important whether E is produced by truly independent source or not.

A. Coupling of indistinguishable photons

To understand the role of partial distinguishability in the entanglement localization, let us first assume that both photons B and E are perfectly indistinguishable. Then, if both the photons leave the linear polarization-insensitive coupling separately, the coupling transformation can be written for any polarization state $|\Psi\rangle_B$ as:

$$\begin{aligned} |\Psi\rangle_B |\Psi\rangle_E &\rightarrow (T - R) |\Psi\rangle_B |\Psi\rangle_E, \\ |\Psi\rangle_B |\Psi_{\perp}\rangle_E &\rightarrow T |\Psi\rangle_B |\Psi_{\perp}\rangle_E - R |\Psi_{\perp}\rangle_B |\Psi\rangle_E. \end{aligned} \quad (1)$$

Both the singlet state $|\Psi_{-}\rangle_{AB}$ as well as ρ_E can be written in the general basis $|\Psi\rangle$ and $|\Psi_{\perp}\rangle$, namely: $|\Psi_{-}\rangle_{AB} = (|\Psi\Psi_{\perp}\rangle_{AB} - |\Psi_{\perp}\Psi\rangle_{AB})/\sqrt{2}$ and $\rho_E = (|\Psi\rangle_E \langle\Psi| +$

$|\Psi_{\perp}\rangle_E \langle\Psi_{\perp}|)/2$. Therefore, it is simple to find that the output state σ_{ind}^I (tracing over photon E) is exactly a mixture of the entangled state with the unpolarized noise (Werner state) [27]:

$$\sigma_{ind}^I = \frac{4F_{ind}-1}{3}|\Psi_{-}\rangle_{AB}\langle\Psi_{-}| + \frac{(1-F_{ind})}{3}\mathbb{1}_A \otimes \mathbb{1}_B, \quad (2)$$

where the fidelity F_{ind} , that is the overlap with the singlet state $|\Psi_{-}\rangle_{AB}$, takes values $0 \leq F_{ind} \leq 1$ and reads:

$$F_{ind} = \frac{(1-3T)^2}{4(1-3T(1-T))}. \quad (3)$$

The state is entangled only if $1/2 < F \leq 1$ and the concurrence [28] reads $C_{ind} = 2F_{ind} - 1$. If $F_{ind} < 1/2$ the entanglement is completely lost and the state (2) is separable. The explicit formula for concurrence is

$$C_{ind}^I = \max\left(0, \frac{3T^2-1}{2(1-3T(1-T))}\right). \quad (4)$$

The probability of this situation is $P_{ind}^I = (T^2 + (T-R)^2 + R^2)/2$ and the condition for entanglement breaking channel is $T < 1/\sqrt{3}$. In order to achieve a maximal violation of Bell inequalities [29], we have to refer to the quantity B_{ind}^I given by the expression

$$B_{ind}^I = \frac{2\sqrt{2}T|1-2T|}{1-3T(1-T)} \quad (5)$$

The violation appears only for $T > 0.68$, imposing a condition on the coupling even more strict.

More generally, all the result that will be presented in the paper can be directly extended for general passive coupling between two modes. It can be represented by Mach-Zehnder interferometer consisting to two unbalanced beam splitters (with transmissivity T_1 and T_2) and two phase shifts $-\phi$ and ϕ separately in arms inside the interferometer. All the results depends only on a single parameter: the probability T that the entangled photon will leave the coupling as the signal, which is explicitly equal to:

$$T = T_1 + T_2 - 2T_1T_2 + \sqrt{T_1T_2R_1R_2} \cos 2\phi. \quad (6)$$

Thus all results, here simply discussed for a beam splitter, are valid for any passive coupling between two photons.

After the measurement of polarization on photon E , let us say by the projection on an arbitrary state $|\Psi\rangle_E$, the state of photons A, B is transformed into

$$\sigma_{ind}^{II} = \frac{1}{P_{ind}^{II}} ((T^2 + (T-R)^2)|T\rangle\langle T| + R^2|\Psi_{\perp}\Psi_{\perp}\rangle\langle\Psi_{\perp}\Psi_{\perp}|) \quad (7)$$

where the state $|T\rangle$ represents the unbalanced singlet state:

$$|T\rangle = \frac{1}{\sqrt{T^2 + (T-R)^2}} (T|\Psi\Psi_{\perp}\rangle - (T-R)|\Psi_{\perp}\Psi\rangle) \quad (8)$$

and $P_{ind}^{II} = T^2 + (T-R)^2 + R^2$. Calculating the concurrence as measure of entanglement, we found

$$C_{ind}^{II} = \frac{T|2T-1|}{1-3(1-T)T} \quad (9)$$

which is always larger than zero if $T \neq 0, 1/2$. It is worth notice that, irrespective to polarization noise in the qubit E , it is possible to probabilistically localized back to the original photon pair A and B a non-zero entanglement for all $T \neq 0, 1/2$.

The basic principle of this process can be understood by comparing Eq. (2) and Eq. (7). The unpolarized noise in Eq. (2) has been transformed to a fully correlated polarized noise in Eq. (7) just by the measurement on E . This measurement can be arbitrary and does not depend on the coupling strength T . Thus, it is not necessary to estimate the channel coupling before the measurement. The positive result comes from the observation that a fully correlated and polarized noise is less destructive to maximal entanglement than the completely depolarized noise. Further, the entanglement localization effect persists even if an arbitrary phase or amplitude damping channel affects photon E after the coupling. If there is still a preferred basis in which the same classical correlation can be kept, it is sufficient for the entanglement localization. Unfortunately, the localized state is entangled but the localization itself is not enough to produce a state violating Bell inequalities. The maximal Bell factor B_{ind}^{II} is identical to (5) although the state has completely changed its structure.

However if T is known then the entanglement of state (7) and the Bell inequality violation can be further increased by the single-copy distillation [15, 16, 17]. First, a local polarization filter can be used to get the balanced singlet state in the mixture. An explicit construction of the single local filter at Bob's side is given by $|\Psi\rangle \rightarrow (T-R)/T|\Psi\rangle, |\Psi_{\perp}\rangle \rightarrow |\Psi_{\perp}\rangle$ for $T > 1/3$. If $T < 1/3$ then a different filtering $|\Psi\rangle \rightarrow |\Psi\rangle, |\Psi_{\perp}\rangle \rightarrow T/(T-R)|\Psi_{\perp}\rangle$ has to be applied. Thus the Werner state (2) is conditionally transformed to a maximally entangled mixed state (MEMS)[30, 31, 32, 37]:

$$\frac{((T-R)^2|\Psi_{-}\rangle\langle\Psi_{-}| + R^2|\Psi_{\perp}\Psi_{\perp}\rangle\langle\Psi_{\perp}\Psi_{\perp}|)}{(T-R)^2 + R^2} \quad (10)$$

where the probability of success is given by $(T-R)^2 + R^2$. Due to symmetry, the same situation arises if the state $|\Psi_{\perp}\rangle$ is detected, just replacing the state $\Psi \leftrightarrow \Psi_{\perp}$. If the local filtering on Bob's side is applied according to the projection, it is possible to reach the MEMS with twice of success probability. Now, a difference between Eq.(10) and Eq. (2) is only in an additive fully correlated polarized noise. Such result can be achieved by an operation on the photon B , while a processing on other photon is not required.

Further local filtration performed on both photons A and B can give maximal entanglement achievable from a single copy. Both Alice and Bob should implement

the filtration $|\Psi\rangle \rightarrow |\Psi\rangle$ and $|\Psi_\perp\rangle \rightarrow \sqrt{\epsilon}|\Psi_\perp\rangle$, where $0 < \epsilon \leq 1$. The filtered state is then

$$\sigma_{ind}^{III} = \frac{1}{4P_{ind}^{III}} (\epsilon(2T-1)^2 |\Psi_-\rangle\langle\Psi_-| + \epsilon^2(1-T)^2 |\Psi_\perp\Psi_\perp\rangle\langle\Psi_\perp\Psi_\perp|) \quad (11)$$

where $P_{ind}^{III} = (\epsilon(2T-1)^2 + \epsilon^2(1-T)^2)/4$ is probability of success. The state has the following concurrence for $T \neq 0, 1/2$

$$C_{ind}^{III}(\epsilon) = \frac{1}{1 + \epsilon \frac{(1-T)^2}{2(1-2T)^2}} \quad (12)$$

As ϵ goes to zero, the concurrence approaches unity, except for $T = 0, 1/2$, where it vanishes. Thus we can get entanglement arbitrarily close to its maximal value for any T (except $T = 0, 1/2$). For $T = 1/2$, it could not appear due to bunching effect between the photons at the beam splitter. Such result can be achieved since we can completely eliminate the fully correlated polarized noise, which is actually completely orthogonal to the single state $|\Psi_-\rangle$. We stress once again that maximal entanglement was probabilistically approached irrespective to the initial polarization noise of the photon E , just by its single-copy localization measurement and single-copy distillation.

If $\epsilon \rightarrow 0$ we get simply $B_{ind}^{III} = 2\sqrt{2}$ for any T , except $T = 0, 1/2$. Since the maximal entanglement allows ideal teleportation of unknown state we can conclude that the linear coupling to the distinguishable photon even in an unknown state could be practically probabilistically reversed. It is interesting to make a comparison with the deterministic localization procedure. To achieve it, we need perfect control of the state of photon E before the coupling. We can know it either a priori or by a measurement on the more complex systems predicting pure state of E . Being $|\Psi\rangle_E$ the state of E after coupling, three-photon state is proportional to $|\Psi\rangle_A (T|\Psi_\perp\Psi\rangle_{BE} - R|\Psi\Psi_\perp\rangle_{BE}) - (T-R)|\Psi_\perp\Psi\Psi\rangle_{ABE}$. This belongs to not-symmetrical W-state, rather than to GHZ states, therefore the maximal entanglement can not be obtained deterministically. It can be done by the projection on $|\Psi\rangle_E$ followed by the single-copy distillation. From this point of view, the unpolarized noise of photon E does not qualitatively change the result of the localization, but only decreases the success rate.

B. Coupling of partially distinguishable photons

Up to now, we have assumed that both photons B and E are indistinguishable in the linear coupling. On the other hand, if they are partially or fully distinguishable, then it is in principle possible to perfectly filter out surrounding photons from the signal photons after the coupling. Although they are in principle partially or fully distinguishable, any realistic attempt to discriminate them would be typically too noisy to offer such

FIG. 2: Concurrence for indistinguishable photon E ($p = 1$): C_{ind}^I without measurement (dotted), C_{ind}^{II} with measurement (dashed), C_{ind}^{III} with measurement and LOCC filtration (full), for $\epsilon = 0.005$.

FIG. 3: Concurrence for distinguishable photon ($p = 0$): C_{dis}^I without measurement (dotted), C_{dis}^{II} with measurement (dashed), C_{dis}^{III} with measurement and LOCC filtration (full)

information. Here we are interested in the opposite situation, when distinguishable photon B and surrounding photon E cannot be practically distinguished after the coupling. It is an open question whether the entanglement localization method can still help us. For simplicity, let us assume a mixture of the previous case with a situation where both the photons B and E are completely distinguishable. The state is mixture $p\sigma_{ind} + (1-p)\rho_{dis}$, where only with probability p the photons are indistinguishable. After the coupling and tracing over photon E , the output state is once more a Werner state (2) with fidelity

$$F(p) = \frac{(4p+5)T^2 - 2(2p+1)T + 1}{4(1-(2+p)T(1-T))} \quad (13)$$

and success probability $P(p) = 1 - (2+p)T(1-T)$. The concurrence is given by $C(p) = 2F(p) - 1$. The entanglement between A and B is lost if

$$p > \frac{T^2 + 2T - 1}{2T(1-T)} \quad (14)$$

and thus for $T < \sqrt{2} - 1$, the entanglement between A and B is lost for any p . The maximal Bell factor

$$B(p) = 2\sqrt{2}T \frac{|T - p(1 - T)|}{1 - (p + 2)(1 - T)T} \quad (15)$$

gives violation of Bell inequalities only if $p \in [0, 1]$ satisfies

$$p < \sqrt{2} + \frac{1}{1 - T} - \frac{1 + \sqrt{2}}{T}. \quad (16)$$

Let us discuss first the entanglement localization for the fully distinguishable photon case ($p = 0$). In this limit, after the coupling the fidelity reads:

$$F_{dis} = \frac{5T^2 - 2T + 1}{4(1 - 2T(1 - T))}, \quad (17)$$

and the concurrence and the maximal violation of Bell inequalities are

$$C_{dis}^I = \frac{T^2 + 2T - 1}{2(1 - 2T(1 - T))}, \quad B_{dis}^I = 2\sqrt{2} \frac{T^2}{T^2 + (1 - T)^2}. \quad (18)$$

The concurrence vanishes for $T < \sqrt{2} - 1$ and the violation of Bell inequalities disappears for $T < 1 + \frac{1}{\sqrt{2}}(1 - \sqrt{1 + \sqrt{2}}) \approx 0.608$. In both cases, the thresholds are lower than for the coupling of indistinguishable photons; the distinguishability of photon E leads to less robust transmission of the quantum resources.

If the projection on $|\Psi\rangle_E$ is performed on the environmental photon after the coupling, the resulting state reads

$$\rho_{dis}^{II} = \frac{1}{P_{dis}^{II}} \left(\frac{T^2}{2} |\Psi_{-}\rangle_{AB} \langle \Psi_{-}| + \frac{R^2}{2} |\Psi_{\perp}\rangle_A \langle \Psi_{\perp}| \otimes \mathbb{1}/2_B \right) \quad (19)$$

where $P_{dis}^{II} = (T^2 + R^2)/2$. Clearly, the additive noisy term in the Eq.(19) is separable and the full correlation in the partially polarized noise (7) does not arise here, in comparison with the fully indistinguishable case. Except for $T = 0$, this state is exhibiting non-zero concurrence

$$C_{dis}^{II} = \frac{T^2}{2T^2 - 2T + 1} \quad (20)$$

which is a decreasing function of T . The state just after the localization does not violate Bell inequalities, since the maximal Bell factor is the same as after the mixing $B_{dis}^{II} = B_{dis}^I$.

Similarly to the previous discussion, projecting on $|\Psi_{\perp}\rangle_E$, we get an identical state, only replacing $\Psi \leftrightarrow \Psi_{\perp}$. This means that even for completely non-interfering photons B and E , a polarization measurement on the photon E can localize entanglement back to photons A and B . To approach it with maximal success rate, local unitary transformations doing $\Psi \leftrightarrow \Psi_{\perp}$ have to be applied if $|\Psi_{\perp}\rangle$ is measured. Similarly to previous indistinguishable case, the photon E is not affected by the amplitude

or phase damping channel. It is only important to keep a preferred basis without any noise influence.

The physical mechanism which models the localization process for coupling of distinguishable photons is different from the previous case. Here, the three-photon mixed state after the coupling is proportional to

$$T^2 |\Psi_{-}\rangle_{AB} \langle \Psi_{-}| \otimes \mathbb{1}/2_E + R^2 |\Psi_{-}\rangle_{AE} \langle \Psi_{-}| \otimes \mathbb{1}/2_B \quad (21)$$

describing just a random swap of the photons B and E at the beam splitter. Although there is no correlation generated by the coupling between photons A and B , contrary to previous case, still a correlation between photons A and E will appear in the second part of expression due to the initial entangled state. It is used to conditionally transform the locally completely depolarized state of photon A to a fully polarized state. Of course, it does not have any impact on the local state of photon B . But it is fully enough to localize entanglement for any T after the projection on photon E . It is rather a non-local correlation effect where the polarization noise is corrected not at photon B but at photon A .

The entanglement can be further enhanced using local filtration and classical communication; in the limit $\epsilon \rightarrow 0$ and introducing optimal filtering given by

$$\begin{aligned} |\Psi_{\perp}\Psi\rangle &\rightarrow \frac{T}{\sqrt{2T^2 - 2T + 1}} |\Psi_{\perp}\Psi\rangle, \\ |\Psi_{\perp}\Psi_{\perp}\rangle &\rightarrow \epsilon |\Psi_{\perp}\Psi_{\perp}\rangle \end{aligned} \quad (22)$$

(whereas all other basis states are preserved) the final state approaches

$$\begin{aligned} \rho_{dis}^{III} &= \frac{1}{2} |\Psi\Psi_{\perp}\rangle_{AB} \langle \Psi\Psi_{\perp}| + \frac{1}{2} |\Psi_{\perp}\Psi\rangle_{AB} \langle \Psi_{\perp}\Psi| \\ &- \frac{T}{2\sqrt{2T^2 - 2T + 1}} (|\Psi\Psi_{\perp}\rangle \langle \Psi_{\perp}\Psi| + \text{h.c.}). \end{aligned} \quad (23)$$

The filtrations turns the state (19) into state (23) which appears as a result of the action of phase damping channel on the input singlet state. The filtrations eliminated the noise component $|\Psi_{\perp}\Psi_{\perp}\rangle_{AB} \langle \Psi_{\perp}\Psi_{\perp}|$ from the state (19) and this ensures the violation of Bell inequalities for the final state (23).

The concurrence approaches $C_{dis}^{III} = \sqrt{C_{dis}^{II}}$, at cost of a decreasing success rate. But, at contrary to the case of two perfectly interfering photons, maximal entanglement cannot be approached for any $T < 1$. This is caused by lack of interference in the entanglement localization for distinguishable photons. Of course, the collective protocols can be still used, since all entangled two-qubit states are distillable to maximally entangled state [15].

A maximal value of the Bell factor

$$B_{dis}^{III} = 2\sqrt{1 + \frac{T^2}{T^2 + (1 - T)^2}} \quad (24)$$

can be achieved if $\epsilon \rightarrow 0$ for any T . Although Bell inequalities are violated in this case for any $T > 0$ the full entanglement cannot be recovered at any single copy.

Also here it is instructive to make a comparison with the case in which the photon E is in the known pure state $|\Psi\rangle_E$. Then after the coupling the three-photon state is proportional to $T^2|\Psi\rangle_{AB}\langle\Psi| \otimes |\Psi\rangle_E\langle\Psi| + R^2|\Psi\rangle_{AE}\langle\Psi| \otimes |\Psi\rangle_B\langle\Psi|$ and after the projection on $|\Psi\rangle_E$, it transforms to $T^2|\Psi\rangle_{AB}\langle\Psi| + \frac{1}{2}R^2|\Psi\rangle_A\langle\Psi| \otimes |\Psi\rangle_B\langle\Psi|$. Since both the contributions are not orthogonal there is no local filtration procedure which could filter out the $|\Psi\rangle_{AB}$ from the noise contribution. Therefore, although we could have a complete knowledge about pure state of the photon E , its distinguishability does not allow to achieve maximal entanglement from the single copy distillation.

For the mixture of both the distinguishable and indistinguishable photons, the concurrence after the measurement is

$$C^I(p) = \max\left(0, \frac{|(1+p)T^2 - pT|}{1 - (2+p)T(1-T)}\right), \quad (25)$$

which is positive if $p \neq T/(1-T)$ and

$$p < \frac{1-T}{T} + \frac{T}{1-T}. \quad (26)$$

Except $T = 0, p/(1+p)$, the last condition is always satisfied since right side has minimum equal to two. Even if the noise is a mixture of distinguishable and indistinguishable photons, it is possible to localize entanglement just by a measurement for almost all the cases. After the application of LOCC polarization filtering, the concurrence can be enhanced up to

$$C^{III}(p, \epsilon) = \frac{2T^2|T - p(1-T)|}{\sqrt{1 - 2(1+p)(1-T)T}(\epsilon(1-T)^2 + 2T^2)}. \quad (27)$$

In the limit of $\epsilon \rightarrow 0$, it approaches

$$C^{III}(p) = \max\left(0, \frac{|T - p(1-T)|}{\sqrt{1 - 2(1+p)T(1-T)}}\right) \quad (28)$$

which is plotted at the top of FIG. 4. The maximal entanglement can be only induced for $p = 1$. Comparing both the discussed cases of the indistinguishable and distinguishable photons, it is evident that it can be advantageous to induce indistinguishability. For example, if they are distinguishable in time, then spectral filtering can help us to make them more distinguishable and consequently, the entanglement can be enhanced more by local filtering.

For partially indistinguishable photons given by parameter p , we get the same value of the Bell factor after the measurement stage as after the mixing stage $B^{II}(p) = B^I(p)$. In the range of parameters p and T where $B^I(p) < 2$ we are not able to violate the Bell inequalities just by measurement although the state just after the measurement changed its structure. The physical reason is that the difference between polarized and unpolarized noise is not enough to guarantee violation

FIG. 4: Top plot shows maximal concurrence $C^{III}(p)$ and bottom plot maximal violation of Bell inequalities $B^{III}(p)$ for the localized state.

of Bell inequalities. We can cross the border of violation of Bell inequalities by performing local single-copy filtration operations generally on both sides. We apply the two stage filtration operations as stated previously. If the filtration parameter

$$\epsilon \in \left(\frac{2T^2 \left(\sqrt{1 - 2(p+1)(1-T)T} - |T - p(1-T)| \right)}{(T-1)^2 \sqrt{1 - 2(p+1)(1-T)T}}, \frac{2T^2 \left(\sqrt{1 - 2(p+1)(1-T)T} + |T - p(1-T)| \right)}{(T-1)^2 \sqrt{1 - 2(p+1)(1-T)T}} \right), \quad (29)$$

analyzed in polarization through a $\frac{\lambda}{2}$ waveplate (wp), a $\frac{\lambda}{4}$ and a PBS. Then the photons are coupled to a single mode fiber and detected by single photon counting module (SPCM) $\{D_A, D_{A'}, D_{B'}, D_B\}$. The output signals of the detectors are sent to a coincidence box interfaced with a computer, which collects the double coincidence rates ($[D_A, D_B]$, $[D_A, D_{B'}]$, $[D_{A'}, D_B]$, $[D_{A'}, D_{B'}]$) and triple coincidence rates ($[D_A, D_B, D_E]$, $[D_A, D_{B'}, D_E]$, $[D_{A'}, D_B, D_E]$, $[D_{A'}, D_{B'}, D_E]$). The detection of triple coincidence ensures the presence of one photon per mode after the BS. In order to determine all the elements of the two-qubit density matrix, an overcomplete set of observables is measured by adopting different polarization settings of the $\frac{\lambda}{2}$ wp and $\frac{\lambda}{4}$ wp positions [36]. The uncertainties on the different observables have been calculated through numerical simulations of counting fluctuations due to the Poissonian distributions. Here and after, we will distinguish the experimental density matrix from the theoretical one by adding a "tilde" $\sim$.

As first experimental step, we have characterized the initial entangled state generated by the NL crystal on mode k_A and k_B , that is the signal to be transmitted through the noisy channel. The overall coincidence rate is equal to about 8.000 coincidences per second. The experimental quantum state tomography of $\tilde{\rho}_{AB}^{in}$ is reported in FIG.7-a, to be compared with the theoretical one $\rho_{AB}^{in} = |\Psi^{in}\rangle_{AB} \langle \Psi^{in}|_{AB}$, where $|\Psi^{in}\rangle = (|HV\rangle + i|VH\rangle)/\sqrt{2}$ (FIG.6-a). Although the generated state differs from the singlet state, all the conclusions from the previous section remains valid. We found a value of the concurrence $\tilde{C}_{in} = (0.869 \pm 0.005)$ and a linear entropy $\tilde{S}_{in} = (0.175 \pm 0.005)$, where the uncertainty on the concurrence has been calculated applying the Monte-Carlo method on the experimental density matrix. The fidelity with the entangled state $|\Psi^{in}\rangle_{AB}$ is $\mathcal{F}(\tilde{\rho}_{AB}^{in}, |\Psi^{in}\rangle_{AB}) = \langle \Psi^{in} |_{AB} \tilde{\rho}_{AB}^{in} | \Psi^{in} \rangle_{AB} = (0.915 \pm 0.002)$. The discrepancy between theory and experiment is mainly attributed to double pairs emission. Indeed by subtracting the accidental coincidences we obtain a concurrence equal to $\tilde{C}'_{in} = (0.939 \pm 0.006)$ and a linear entropy of $\tilde{S}'_{in} = (0.091 \pm 0.006)$. The fidelity with the entangled state $|\Psi^{in}\rangle_{AB}$ is then equal to $F'(\tilde{\rho}_{AB}^{in}, |\Psi^{in}\rangle_{AB}) = (0.949 \pm 0.003)$. Minor sources of imperfections related to the generation of our entangled state are the presence of spatial and temporal walk-off due to the non linearity of the BBO crystal as well as a correlation in wavelength of the generated pairs of photons.

B. Coupling of distinguishable photons

The experiment with distinguishable photons has been achieved by injecting a single photon E with a randomly chosen mutual delay with photon B of $\Delta t \gg \tau_{ind} = 300fs$. We note that the resolution time t_{det} of the detector is $t_{det} \gg \Delta t$, hence it is not technologically pos-

sible to individuate whether the detected photon belongs to the environment or to the entangled pair. To carry out the experiment we adopted a beam splitter with $T = 0.40$ which, according to the theoretical prediction (see FIG. 3), allows to study the entanglement localization process.

Since multi-photon contributions represent the main source of imperfections in our calculations, we have subtracted their contributions in all the experimental data reported for the density matrices of each step of the protocol.

I) Mixing

Without any access to the environmental photon, after the mixing on the BS, once there is one photon per output mode, the theoretical input state $\rho^{in} = |\Psi^{in}\rangle \langle \Psi^{in}|$ evolves into a noisy state represented by the density matrix ρ_{dis}^I , written in the basis $\{|HH\rangle, |HV\rangle, |VH\rangle, |VV\rangle\}$ as:

$$\rho_{dis}^I = \frac{1}{4P_{dis}^I} \begin{pmatrix} \alpha & 0 & 0 & 0 \\ 0 & \beta & i\xi & 0 \\ 0 & -i\xi & \gamma & 0 \\ 0 & 0 & 0 & \delta \end{pmatrix} \quad (33)$$

with $\alpha = \delta = R^2$, $\beta = \gamma = R^2 + 2T^2$, $\xi = 2T^2$ and $P_{dis}^I = R^2 + T^2$, where $R = 1 - T$ indicates the reflectivity of the beam splitter. This matrix, shown in FIG.(6-I), exhibits theoretically concurrence $C_{dis}^I = \max(0, \frac{2T^2 - R^2}{2P_{dis}^I})$. Because of the interaction with noise, ρ_{dis}^I does not exhibit entanglement ($C_{dis}^I = 0$) and is highly mixed with linear entropy equal to $S_{dis}^I = 0.90$. Afterwards we analyze experimentally how the entangled state is corrupted due to the coupling with the photon E . In this case no-polarization selection is performed on mode k_E . The experimental density matrix $\tilde{\rho}_{dis}^I$ is shown in FIG.(7-I). As expected, it exhibits $\tilde{C}_{dis}^I = 0$, and $\tilde{S}_{dis}^I = (0.89 \pm 0.01)$. The fidelity with theory is high: $\tilde{F}_{dis}^I = F(\tilde{\rho}_{dis}^I, \rho_{dis}^I) = (0.997 \pm 0.006)$, with $F(\rho, \sigma) = \text{Tr}^2[(\sqrt{\rho\sigma}\sqrt{\rho})^{1/2}]$. In this case, due to the coupling the entanglement is completely redirected and no quantum distillation protocol can be applied to restore entanglement between photons A and B .

II) Measurement

As no selection has been performed on the photon E before the coupling, a multi-mode photon E interacts with the entangled photon B . After the interaction, a single mode fiber has been inserted on the output mode of the BS in order to select only the output mode connected with the entanglement breaking. Let us consider the case in which the photon on mode k_E is measured in the state $|H\rangle_E$. After the measurement, the density matrix ρ_{dis}^I evolves into an entangled one described by the density matrix ρ_{dis}^{II}

$$\rho_{dis}^{II} = \frac{1}{4P_{dis}^{II}} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \beta & i\xi & 0 \\ 0 & -i\xi & \gamma & 0 \\ 0 & 0 & 0 & \delta \end{pmatrix} \quad (34)$$

where $\delta = R^2$, $\beta = T^2$, $\gamma = R^2 + T^2$, $\xi = T^2$: FIG.(6-II). In this case the concurrence reads $C_{dis}^{II} = \frac{T^2}{2P_{dis}^{II}}$ with $P_{dis}^{II} = \frac{P_{dis}^I}{2}$. The entanglement is localized back for all the values of $T \neq \{0, \frac{1}{2}\}$ but, as shown in the graph, the elements of the matrix are fairly unbalanced. According to theory, we expect a localization of the entanglement with $C_{dis}^{II} = 0.32$, and success rate $P_{dis}^{II} = 0.27$. Experimentally we obtain $\tilde{C}_{dis}^{II} = (0.19 \pm 0.02) > 0$, a fidelity with the theoretical density matrix ρ_{dis}^{II} equal to $\tilde{F}_{dis}^{II} = (0.96 \pm 0.03)$, while the mixedness of the state decreases $\tilde{S}_{dis}^{II} = (0.72 \pm 0.02)$ to be compared to theoretical prediction $S_{dis}^{II} = 0.74$. This is achieved at the cost of a probabilistic implementation where the probability of success reads: $\tilde{P}_{dis}^{II} = (0.26 \pm 0.01)$.

FIG. 6: (Color online) Theoretical density matrix for distinguishable photons, enlightening the evolution of ρ through each step of the entanglement localization protocol.

III) Filtration

The filtration is introduced onto the mode k_A and k_B , attenuating the vertical polarization, in order to increase the concurrence and symmetrizing the density matrix by a lowering of the $|VV\rangle\langle VV|$ component in ρ_{dis}^{II} : FIG.(6-

II). After filters F_A and F_B , the density matrix reads:

$$\rho_{dis}^{III} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \epsilon\beta & i\epsilon\xi & 0 \\ 0 & -i\epsilon\xi & \epsilon\beta & 0 \\ 0 & 0 & 0 & \epsilon^2\delta \end{pmatrix} \quad (35)$$

where $\beta = T^2$, $\delta = R^2$, $\xi = \frac{T^3}{\sqrt{T^2 + R^2}}$. The concurrence reads $C_{dis}^{III} = \frac{2\epsilon\xi}{2\epsilon\beta + \epsilon^2\delta}$ while the probability of success of the protocol is equal to $P_{dis}^{III} = 2\epsilon\beta + \epsilon^2\delta$. The intensity of filtration is quantified by the parameter $0 < \epsilon \leq 1$, connected to the attenuation of V polarization. The concurrence has a limit for asymptotic filtration ($\epsilon \rightarrow 0$) lower than unity and maximal entanglement cannot be approached. Of course, the collective protocols can be still used, since all entangled two-qubit state are distillable to a singlet one. By setting the following attenuation values $A_A^V = 0.33$, $A_A^H = 1$, the theory predicts the achievement of ρ_{dis}^{III} (FIG.(6-III)) with the mixedness $S_{dis}^{III} = 0.76$ and the concurrence $C_{dis}^{III} = 0.42$. The probability of success of the filtration operation is $P_{dis}^{III} = 0.43$ leading to an overall probability of success of the entanglement restoration $P_{total} = P_{dis}^{II} P_{dis}^{III} = 0.12$. The highest concurrence value which can be obtained with the coupling $T = 0.40$ is equal to $C = 0.55$ for $P_{total} \rightarrow 0$. Experimentally we achieve the state shown in FIG.(7-III) with a fidelity $\tilde{F}_{dis}^{III} = (0.89 \pm 0.06)$ and measure a concurrence equal to $\tilde{C}_{dis}^{III} = (0.28 \pm 0.02) > \tilde{C}_{dis}^{II}$ while $\tilde{P}_{dis}^{III} \tilde{P}_{dis}^{II} = (0.11 \pm 0.01)$ and $\tilde{S}_{dis}^{III} = (0.70 \pm 0.02)$. The experimental results shown above demonstrate the localization protocol validity, indeed a channel redirecting entanglement can be corrected to a channel preserving relatively large amount of the entanglement.

Let's explain the choice of introducing experimentally just one set of filtration instead of two. The glasses close to Brewster's angle attenuate the V polarization. Let ϵ be the intensity of attenuation, the $|VH\rangle$ element of the density matrix will be attenuated by a factor $\sqrt{\epsilon}$. Even if the theory expects an element $|HH\rangle$ close to zero, in the experimental case we obtain a non-zero element due to the intensity of the coherent radiation, revealed by double photons contributions. Hence a filtration of ϵ on both modes, since it introduces an attenuation of ϵ on the element $|VV\rangle$ and of $\sqrt{\epsilon}$ on both the elements $|HV\rangle$ and $|VH\rangle$, would bring to a wider comparability between $|HH\rangle$ and $|HV\rangle$ elements, leading to a lower concurrence.

C. Coupling of indistinguishable photons

In order to exploit the regime where our localization protocol works best, we let the signal photon and the noise one be spatially, spectrally and temporal perfectly indistinguishable in the coupling process. A good spatial overlap is achieved by selecting the output modes through single mode fibers.

I) Mixing.

FIG. 7: (Color online) Experimental density matrix for distinguishable photons: **(a)** $\tilde{\rho}^{in}$, **(I)** $\tilde{\rho}_{dis}^I$, **(II)** $\tilde{\rho}_{dis}^{II}$, **(III)** $\tilde{\rho}_{dis}^{III}$. For each tomographic setting the measurement lasts from 5 s **(a)** to 30 minutes **(III)**, the last case corresponding to about 500 triple coincidence. Contributions due to triple accidental coincidences have been subtracted from experimental data.

In the fully indistinguishable photons regime, we indicate with σ_{ind}^I the density matrix after the mixing on the BS , which is separable for $T < 1/\sqrt{3}$, as shown in FIG. 2. The output state is a mixture of the initial state $|\Psi^{in}\rangle\langle\Psi^{in}|$ and the fully mixed one [27]: FIG.8-I.

$$\sigma_{ind}^I = \frac{1}{4P_{ind}^I} \begin{pmatrix} \alpha & 0 & 0 & 0 \\ 0 & \beta & i\xi & 0 \\ 0 & -i\xi & \gamma & 0 \\ 0 & 0 & 0 & \delta \end{pmatrix} \quad (36)$$

with $\alpha = \delta = R^2$, $\beta = \gamma = T^2 + (T-R)^2$, $\xi = -T(T-R)$

II) Measurement.

A measurement is carried out on the environmental mode through the projection on $|H\rangle_{E'}$. Thus the state σ_{ind}^I evolves into σ_{ind}^{II} :

$$\sigma_{ind}^{II} = \frac{1}{4P_{ind}^{II}} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \beta & i\xi & 0 \\ 0 & -i\xi & \gamma & 0 \\ 0 & 0 & 0 & \delta \end{pmatrix} \quad (37)$$

FIG. 8: (Color online) Theoretical density matrix for perfectly indistinguishable photons interacting on the BS .

with $\beta = T^2$, $\gamma = T^2 + (T-R)^2$, $\delta = R^2$, $\xi = -T(T-R)$. The state is conditionally transformed into a maximally entangled state (MEMS) [37]: see FIG.(9-II). In particular, it is found $C_{ind}^{II} = \frac{T|T-R|}{2P_{ind}^{II}}$ and $P_{ind}^{II} = \frac{T^2 + (T-R)^2 + R^2}{4}$.

III) Filtration

Due to the strong asymmetry of σ_{ind}^{II} a filter is introduced either on Alice or Bob mode, depending on the value of T . If $T > |2T-1|$, filter F_B acts on Bob mode, as $|H\rangle_B \rightarrow \frac{2T-1}{T}|H\rangle_B$, while if $T < |2T-1|$, the filter acts on Alice mode, as $|V\rangle_A \rightarrow \frac{T}{2T-1}|V\rangle_A$. In order to increase the concurrence, a second filter is inserted on both Alice and Bob mode, which attenuates the vertical polarization component: $|V\rangle \rightarrow \sqrt{\epsilon}|V\rangle$. The filters F_A and F_B transform the density matrix into σ_{ind}^{III} :

$$\sigma_{ind}^{III} = \frac{1}{4P_{ind}^{III}} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \epsilon\alpha & i\epsilon\alpha & 0 \\ 0 & -i\epsilon\alpha & \epsilon\alpha & 0 \\ 0 & 0 & 0 & \epsilon^2\delta \end{pmatrix} \quad (38)$$

where $\alpha = T^2$, $\delta = \left(\frac{TR}{R-T}\right)^2$, for $T < |2T-1|$ and

$\alpha = (2T - 1)^2$, $\delta = R^2$, for $T > |2T - 1|$: FIG.8-II. The concurrence has value $C_{ind}^{III} = \frac{2\epsilon\alpha}{2\epsilon\alpha + \epsilon^2\delta}$ while the probability reads $P_{ind}^{III} = \frac{2\epsilon\alpha + \epsilon^2\delta}{4}$. Hence in the limit of asymptotic filtration ($\epsilon \rightarrow 0$), the concurrence reaches unity except for $T = 1/2$ [37].

D. Coupling of partially indistinguishable photons

Let us now face up to a model which contemplates a situation close to the experimental one. In fact a perfect indistinguishability between the photons B and E is almost impossible to achieve experimentally. We consider the density matrix τ_{AB} of the state shared between Alice and Bob after the coupling, as a mixture arising from coupling with a partially distinguishable noise photon. The degree of indistinguishability is parametrized by the probability p that the fully depolarized photon E is completely indistinguishable from the photon E .

In order to maximize the degree of indistinguishability between the photon of modes k_B and k_E mixed on the beam splitter BS we adopt narrower interference filters and single mode fibers on the output modes. Hence we insert interference filters on mode $k_{B'}$ and $k_{E'}$, with $\Delta\lambda = 1.5nm$. Referring to the previous nomenclature, the density matrix τ can be written as: $\tau_{AB} = p\sigma_{ind} + (1-p)\rho_{dis}$. As first step, we have estimated the degree of indistinguishability between the photon belonging to mode k_B and the one associated to k_E . This measurement has been carried out by realizing an Hong-Ou-Mandel interferometer [38] adopting a balanced 50 : 50 beam splitter instead of BS . The photons on modes $k_{B'}$ and $k_{E'}$ are measured in the same polarization state $|H\rangle$. The visibility of the Hong-Ou-Mandel dip has been measured to be $V = (0.67 \pm 0.02)$. By subtracting estimated double pairs contributions to the three-photon coincidence we have obtained a value of the visibility (0.75 ± 0.02) . We attribute the mismatch with the unit value to a different spectral profile between the coherent beam and the fluorescence, which induces a distinguishability between photons on the input modes of the beam splitter. From the visibility of the dip, we estimate a value of p equal to (0.85 ± 0.05) . Hence we have checked the Hong-Ou-Mandel interference with the unbalanced beam splitter BS , and we have obtained a visibility of (0.40 ± 0.02) . This result has been compared to a theoretical visibility V previously calculated considering the expression $V = p \frac{2RT}{R^2 + T^2} = (0.62 \pm 0.05)$ with p as indicated by the Hong-Ou-Mandel experiment, and $T = 0.3$. To carry out the experiment the optical delay has been set in the position $\Delta t = 0$. The mismatch between the two visibilities are due to multi-photon contributions. Indeed by taking into account the accidental coincidence we have estimated $V = (0.49 \pm 0.03)$.

I) Mixing.

Analogously to what has been showed in the distinguishable case, after the mixing on the BS , once there is one photon per output mode, the input state evolves

FIG. 9: (Color online) Experimental density matrix for partially indistinguishable photons: $\tilde{\tau}$ with $p = 0.85$. **II)** $\tilde{\tau}^{II}$, **III)** $\tilde{\tau}^{III}$.

into a noisy state represented by the density matrix $\tilde{\tau}^I$. The experimental density matrix is characterized by a fidelity with theory : $F(\tilde{\tau}^I, \tau^I) = (0.86 \pm 0.02)$ and vanishing concurrence ($\tilde{C}_I = 0$).

II) Measurement.

After measuring the photon on mode $k_{E'}$, the density matrix $\tilde{\tau}^I$ evolves into $\tilde{\tau}^{II}$: FIG.(9-II). The entanglement is localized with a concurrence equal to $\tilde{C}_{II} = (0.15 \pm 0.03) > 0$ to be compared with $C_{II} = 0.22$; in this case the probability of success reads $\tilde{P}_{II} = (0.22 \pm 0.01)$, while theoretically we expect $P_{II} = 0.2$. The fidelity with the theoretical state is $F(\tilde{\tau}^{II}, \tau^{II}) = (0.96 \pm 0.01)$.

III) Filtration.

Applying experimentally the filtration with the parameters $A_A = 0.12$, and $A_B = 0.30$ we obtain the state shown in FIG.(9-III). Hence we measure a higher concurrence $\tilde{C}_{III} = (0.50 \pm 0.10) > \tilde{C}_{II}$ while the expected theoretical value is $C_{III} = 0.47$. The filtered state has $F(\tilde{\tau}^{III}, \tau^{III}) = (0.92 \pm 0.04)$, and is post-selected with an overall success rate equal to $P_{total} = \tilde{P}_{III}\tilde{P}_{II} = (0.10 \pm 0.01)$, where theoretically $P_{III}P_{II} = 0.09$. This is a clear experimental demonstration of how an induced indistinguishability enhances the localized concurrence.

IV. CONCLUSION

In summary, we have discussed the role of distinguishability in an elementary polarization entanglement three-photon localization protocol, both theoretically and experimentally, especially for the cases of total loss of entanglement. Theoretically, a full indistinguishability of noisy surrounding photon and one photon from the maximally entangled state of two photons is a necessary con-

dition for perfect entanglement localization. Moreover, also for the partially indistinguishable or even fully distinguishable photon the localization protocol is still able to restore non-zero entanglement. Using local single-copy polarization filters, the entanglement can be enhanced even to violate the Bell inequalities. The generalization of the results to linear polarization sensitive coupling is also enclosed. Experimentally, the localization of entanglement is demonstrated for the coupling between fully distinguishable photons as well as for the highly (but still partially) indistinguishable photons. The restoration of entanglement after its previous break was experimentally verified, also the positive role of the indistinguishability induced by the spectral filters has been experimentally checked. These results clearly show the broad applicability of the basic element of the polarization-entanglement localization protocol in realistic situations, where the surrounding uncontrollable noisy system exhibiting just moderate indistinguishability of photons completely destroys the entanglement due to the coupling process. In these cases, the collective entanglement distillation method without a measurement on the surrounding system can not restore any entanglement out of the coupling.

In this paper we extensively discuss the simplest proof-of-principle entanglement localization method with a novel focus just to the effect caused by the indistinguishability of the single surrounding photon. The entanglement localization after the multiple single interactions with the photons is a natural step of further investigation. An open question is whether after such multiple decoherence events on both sides of the entangled state, non-zero entanglement can be as well always localized back just by local measurements and classical communication, or a collective localization measurement will be required. Further, an extension from fixed number of surrounding particles to randomly fluctuating number of the surrounding particles will be interesting. Another interesting direction is to analyze the entanglement localization after another kind of the coupling of partially indistinguishable objects, especially between atoms/ions and light or between individual atoms or ions. This gradual investigation will give a final answer to an important physical question: how to manipulate quantum entanglement distributed by the coupling to noisy (in)distinguishable complex environments.

V. APPENDIX A

To describe a linear coupling (beam splitter) with different transmissivity for vertical and horizontal polarization, we use the amplitude transmissivities t_v and t_h . The intensity transmissivities are then $T_V = t_v^2$ and $T_H = t_h^2$ and the previous result can be obtained taking $T = T_V = T_H$.

FIG. 10: Concurrence before the measurement for indistinguishable (left) and distinguishable (right) couplings.

FIG. 11: Concurrence after the measurement (left) and after the filtration with $\epsilon = 0.1$ (right) for indistinguishable photons (indistinguishable coupling).

A. Coupling of indistinguishable photons

After the mixing of indistinguishable photons B and E on the beam splitter, without any access to the photon E , the single state transforms to the mixed state (if two photons leave separately) exhibiting the concurrence

$$C_{ind}^I = \max \left(0, \frac{2t_v t_h |t_h^2 - 1 + t_v^2| - (1 - t_v^2)(1 - t_h^2)}{2P_{ind}^I} \right), \quad (39)$$

where $P_{ind}^I = (2t_v^2 t_h^2 + (1 - 2t_v^2)^2 + (1 - 2t_h^2)^2 + 2(1 - t_v^2)(1 - t_h^2))/4$ is the success probability. The concurrence is depicted on FIG. 9, there is evidently a large area where the concurrence vanishes completely and the entanglement is lost between A and B .

To restore the entanglement a general projection measurement can be considered on the photon E . But it is too complex to find an optimal projection analytically, rather the optimal measurement can be found numerically, for the particular values of t_v and t_h . On the other hand, it is possible to find a sufficient condition to restore the entanglement for some particular orientation of the measurement. Let us assume the projection of the photon E on the state $|V\rangle$. Then the state σ_{ind} changes and exhibits the concurrence

$$C_{ind}^{II} = \frac{t_h t_v |1 - 2t_v^2|}{2P_{ind}^{II}}, \quad (40)$$

where $P_{ind}^{II} = (t_v^2 t_h^2 + (1 - 2t_v^2)^2 + (1 - t_v^2)(1 - t_h^2))/4$ is

the success rate. Such state is always entangled except $t_h = 0$ or $t_v^2 = 1/2, 0$ and can be further filter out by the filter F1 on photon B which makes $|V\rangle \rightarrow \frac{2t_v^2-1}{t_v t_h} |V\rangle$ for $t_h > \frac{|2t_v^2-1|}{t_v}$ or by the filter F1 on photon A $|H\rangle \rightarrow \frac{t_v t_h}{2t_v^2-1} |H\rangle$ for $t_h < \frac{|2t_v^2-1|}{t_v}$ and subsequently, the filter F2 attenuating horizontal polarization $|H\rangle \rightarrow \sqrt{\epsilon} |H\rangle$, applied to both photons A and B. As result, the state is transformed by both types of filtering to a new state with the corresponding concurrence

$$C_{ind}^{III}(\epsilon) = \frac{\epsilon(1-2t_v^2)^2}{2P_{coh1}^{III}} = \frac{\epsilon t_v^2 t_h^2}{2P_{coh2}^{III}}, \quad (41)$$

where $P_{coh1}^{III} = (2\epsilon(1-2t_v^2)^2 + \epsilon^2(1-t_v^2)(1-t_h^2))/4$ is the success rate of the localization using the first type of filtration F1 on photon B and $P_{coh2}^{III} = (2\epsilon(t_v t_h)^2 + \epsilon^2(1-t_v^2)(1-t_h^2))/(1-2t_v^2)^2)/4$ is the success rate of the restoration using the second type of filtration on photon A. The concurrence approaches unity as $\epsilon \rightarrow 0$. The similar results can be obtained for the projection of the photon E on the state $|H\rangle$, only the substitution $t_h \leftrightarrow t_v$ is necessary. In conclusion, except the cases $t_v^2, t_h^2 = 1/2$, the entanglement can be always localized and enhanced arbitrarily close to maximal pure entangled state, at cost of the success rate, similarly to previous analysis. The concurrences after the measurement and the one after the filtration in the localization procedure are depicted on FIG. 10.

B. Coupling of distinguishable photons

For distinguishable photons, without any access to the photon E , after the mixing at the beam splitter the singlet state transforms to a state exhibiting the concurrence

$$C_{dis}^I = \max\left(0, \frac{t_h t_v (t_h^2 + t_v^2) - (1-t_v^2)(1-t_h^2)}{2P_{dis}^I}\right), \quad (42)$$

where $P_{dis}^I = (2(1-t_v^2)(1-t_h^2) + (1-t_h^2)^2 + t_h^2(t_h^2 + t_v^2) + (1-t_v^2)^2 + t_v^2(t_h^2 + t_v^2))/4$ is the probability of success. Similarly, there is a large area of the parameters in which the concurrence vanishes and the entanglement is lost between A and B , as can be seen from FIG. 9.

Similarly, it is sufficient to localize entanglement by the projection of the environmental photon on the state $|V\rangle$. After the successful projection, the mixed state has concurrence

$$C_{dis}^{II} = \frac{t_h t_v^3}{2P_{dis}^{II}}, \quad (43)$$

where $P_{dis}^{II} = (t_h^2 t_v^2 + t_v^4 + (1-t_v^2)^2 + (1-t_v^2)(1-t_h^2))/4$ is the success rate of the projection. Except trivial $t_v, t_h = 0$, the entanglement is always localized by the projection

on the environment. But for this case, optimal filtration by F1 and F2 defined as $|V\rangle \rightarrow \frac{t_v t_h}{\sqrt{t_v^4 + (1-t_v^2)^2}} |V\rangle$ and

FIG. 12: Concurrence after the measurement (left) and after the filtration with $\epsilon = 0.1$ (right) for distinguishable coupling.

FIG. 13: Success rate after the filtration with $\epsilon = 0.1$ for indistinguishable photons (left) and distinguishable photons (right)

$|H\rangle \rightarrow \sqrt{\epsilon} |H\rangle$ produces the state with overall probability of success $P_{dis}^{III} = (2\epsilon t_v^2 t_h^2 + \epsilon^2(1-t_v^2)(1-t_h^2))/4$, which gives the concurrence

$$C_{dis}^{III}(\epsilon) = \frac{\epsilon t_v^4 t_h^2}{2P_{dis}^{III} \sqrt{t_v^4 + (1-t_v^2)^2}} \quad (44)$$

In the limit $\epsilon \rightarrow 0$ it gives the maximal concurrence

$$C_{dis}^{III} = \frac{t_v^2}{\sqrt{t_v^4 + (1-t_v^2)^2}}. \quad (45)$$

In a similar way as in the symmetrical case, the maximal entanglement cannot be approached if the photon E is in principle distinguishable. The concurrence before and after the filtration is depicted on FIG. 11. Success rates after the filtration for both the indistinguishable and distinguishable photons are plotted in FIG. 12.
